Abstract

This work aims to provide standard formulations for direct minimization approaches on various types of static problems of continuum mechanics. Particularly, form-finding problems of tension structures are discussed in the first half and the large deformation problems of continuum bodies are discussed in the last half. In the first half, as the standards of iterative direct minimization strategies, two types of simple recursive methods are presented, namely the two-term method and the three-term method. The dual estimate is also introduced as a powerful means of involving equally constraint conditions into minimization problems. As examples of direct minimization approaches on usual engineering issues, some form finding problems of tension structures which can be solved by the presented strategies are illustrated. Additionally, it is pointed out that while the two-term method sometimes becomes useless, the three-term method always provides remarkable rate of global convergence efficiency. Then, to show the potential ability of the three-term method, in the last part of this work, some principle of virtual works which usually appear in the continuum mechanics are approximated and discretized in a common manner, which are suitable to be solved by the three-term method. Finally, some large deformation analyses of continuum bodies which can be solved by the three-term method are presented.

Keywords: Two-term method, Three-term method, Multiplier method, Dual Estimate, Principle of virtual work, Direct Minimization

1. Introduction

Within this work, standard formulations for solving various types of static problems of continuum bodies by the direct minimization methods are presented. The direct minimization methods are always associated with static mechanics via **principle of virtual work**. For example, the direct minimization approaches are sometimes very effective on solving form-finding problems of tension structures[1]. In particular, the aim of this work is to present the basic strategies such as the **three-term method** and the **dual estimate**, and to illustrate various types of static problems that can be solved by using them.

In section 2, as the standard recursive direct minimization methods, the **two-term method** and the **three-term method** are described. While the former is basically identical with the steepest decent method and the latter is with the dynamic relaxation method, some differences are pointed out. In addition, via discussion of a form-finding problem of a simple cable-net structure as a typical example, the relation over the **principle of virtual work**, the **stationary condition**, and the **standard search direction** is clarified. Furthermore, the **dual estimate** is proposed as a powerful means of involving constraint conditions into direct minimization approaches. Then, form-finding analyses of a tensegrity structure and a tensioned membrane

structure are illustrated as examples of minimization problems with constraint conditions.

In section 3, more general cases of static problems of continuum bodies are taken into account. First, the discrete **principle of virtual work**, the **stationary condition**, and the **standard search direction** are formulated as the result of standard procedures. They can be positioned as the generalizations of those appeared in section 2 and enables the direct minimization methods feasible on general cases of static problems of continuum bodies. Finally, some large deformation analyses of continuum bodies which can be solved by the **three-term method** are illustrated.

2. Two-term method and three-term method

2.1. Direct minimization approaches without constraint conditions

Suppose a form-finding problem of a prestressed cable-net structure which can be stabilized via introducing prestress (see Fig. 2.1). For example, any solutions of the following stationary problem of a functional can be used as such a form:

$$\Pi(\mathbf{x}) = \sum_j w_j L_j^2(\mathbf{x}) \rightarrow \text{stationary}, \quad (2.1)$$

where w_j, L_j denote the weight coefficient and the length of the j -th cable respectively. The weight coefficients are the parameters which are assigned with the aim of varying the form by varying them, and they are treated as constant in the following formulations. In addition, $\mathbf{x}$ is a column vector which contains the unknown variables $\{x_1, \dots, x_n\}$.

[☆]This work supplements Ref. [1], particularly about computational algorithms which was used in it.

Figure 2.1: Form-finding of Cable-net Structure

In this work, $\mathbf{x}$ and corresponding gradient vector are always arranged as

$$\mathbf{x} \equiv \begin{bmatrix} x_1 & \cdots & x_n \end{bmatrix}^T, \text{ and } \nabla f \equiv \begin{bmatrix} \frac{\partial f}{\partial x_1} & \cdots & \frac{\partial f}{\partial x_n} \end{bmatrix}. \quad (2.2)$$

By the authors, it has been pointed out [1] that solving Eq.(2.1) by the direct minimization methods can be positioned as that an equilibrium equation provided by the force density method [2] is represented in a different manner firstly, and then the equilibrium equation is solved by a direct minimization method which differ from the method proposed in the original force density method.

In this work, the unknown variables $\{x_1, \cdots, x_n\}$ are always assumed as denoting the Cartesian coordinates of the free nodes. In addition, remark that those of the fixed nodes are eliminated beforehand from $\mathbf{x}$ and they are directly substituted into each L_j .

When Eq.(2.1) is solved by the direct minimization methods, $\Pi(\mathbf{x})$ is usually called the objective function. Additionally, the direction of greatest rate of increase of Π , namely

$$\mathbf{r} = \frac{\nabla \Pi^T}{|\nabla \Pi|} \quad (2.3)$$

is usually adopted as the **standard search direction**.

The stationary condition of Eq.(2.1) is as follows:

$$\nabla \Pi = \mathbf{0} \Leftrightarrow \sum_j 2w_j L_j \nabla L_j = \mathbf{0}. \quad (2.4)$$

Here, taking the inner product of Eq. (2.4) with arbitrary column vector $\delta \mathbf{x}$, namely

$$\delta \mathbf{x} = \begin{bmatrix} \delta x_1 & \cdots & \delta x_n \end{bmatrix}^T, \quad (2.5)$$

the **principle of virtual work** can be obtained as:

$$\delta w = \sum_j 2w_j L_j \delta L_j = 0, \quad (2.6)$$

or the **variational principle** can be found has

$$\delta \Pi = 0, \quad (2.7)$$

where

$$\delta f \equiv \nabla f \cdot \delta \mathbf{x} \quad (2.8)$$

is the variation of f . Due to the arbitrariness of $\delta \mathbf{x}$, Eq. (2.6) and Eq. (2.7) are always equivalent with Eq. 2.4. It is amazing that the common frameworks which are provided by the classic mechanics, such as the **principle of virtual work** and the **variational principle**, can be even found in such a minor force density method.

On the other hand, the **principle of virtual work** for self-equilibrium cable-net structures can be expressed as

$$\delta w = \sum_j n_j \delta L_j = 0, \quad (2.9)$$

where n_j denotes the tension of j -th cable. By comparing Eq. (2.6) and Eq. (2.9), when $\Pi(\mathbf{x})$ is stationary, at least one self-equilibrium state can be found as

$$\begin{bmatrix} n_1 & \cdots & n_m \end{bmatrix} = \begin{bmatrix} 2w_1 L_1 & \cdots & 2w_m L_m \end{bmatrix}. \quad (2.10)$$

Therefore, any solution of Eq. (2.1) can be used as a form of cable-net structures that can be prestressed.

When the **standard search direction** is given by Eq. (2.3), one of the simplest recursive direct minimization methods is given by

$$\begin{aligned} \mathbf{r}_{\text{Current}} &= \frac{\nabla \Pi^T}{|\nabla \Pi|} \circ (\mathbf{x} = \mathbf{x}_{\text{Current}}), \\ \mathbf{x}_{\text{Next}} &= \mathbf{x}_{\text{Current}} - \alpha \mathbf{r}_{\text{Current}}, \end{aligned} \quad (2.11)$$

which is called the **two-term method** in this work. Here, "Current" and "Next" are the current and the next step numbers. As is immediately noticed, the **two-term method** is basically identical with the steepest decent method. The main differences are as follows:

- The **standard search direction** is always normalized.
- Step-size factor α is a parameter which is assigned with the aims of adjusting the rate of convergence and treated as constant in the formulations. (In the steepest decent method, step-size is usually determined by line-search algorithm)

The aim of the normalization of the **standard search direction** is to prevent the divergence of the computation. Moreover, without using some computational algorithms to determine α , if α is treated as constant in the formulation and to be adjusted

by somebody via GUI, appropriate α can be found easily. Actually, it was really easy and intuitive operation to determine α via GUI.

By the way, the rate of global convergence efficiency of the **two-term method** is not basically good, as of the steepest decent method usually is. Because it is supposed that the computation would usually start from a point which places far from the exact solution, the rate of global convergence efficiency must be improved. Then, the following remedy of the **two-term method** sometimes provides a remarkable improvement of global convergence efficiency:

$$\begin{aligned} \mathbf{r}_{\text{Current}} &= \frac{\nabla \Pi^T}{|\nabla \Pi|} \circ (\mathbf{x} = \mathbf{x}_{\text{Current}}), \\ \mathbf{q}_{\text{Next}} &= 0.98 \mathbf{q}_{\text{Current}} - \alpha \mathbf{r}_{\text{Current}}, \\ \mathbf{x}_{\text{Next}} &= \mathbf{x}_{\text{Current}} + \alpha \mathbf{q}_{\text{Next}}, \end{aligned} \quad (2.12)$$

which is called the **three-term method** in this work. When $\{\mathbf{x}, \mathbf{q}, \mathbf{r}\}$ are thought as $\{\text{position, velocity, acceleration}\}$, Eq. (2.12) can be positioned as one kind of equation of motion with a damping term, therefore the basic idea of the **three-term method** is almost identical with the dynamic relaxation method[7]. However, as same as in the **two-term method**, the **standard search direction** is also normalized in the **three-term method**. Then, it is better to interpret the **three-term method** as just one of the recursive direct minimization methods and is not being based on dynamic mechanics. The factor 0.98 which can be found on the second line means that 2% of $\mathbf{q}$ is compulsory cut in each step, which can be interpreted as one kind of damping factor. This factor is having no basis and being determined by some experience.

As is mentioned above, because the **three-term method** is not based on the dynamics, the following consideration is not precise; however, the high rate of global convergence efficiency provided by the **three-term method** can be understood intuitively when it is explained with terms of energy conservation law. Namely, due to the elimination of 2% of $\mathbf{q}$ in each step, the total energy of the system is compulsory exhausted gradually, then Π and $\mathbf{q}$ would shortly reach to the minimum value and 0.

An numerical model for verification of the **two-term** and the **three-term method** is provided by Fig. 2.1, which consists of 5 fixed nodes and 220 tension members. The coordinates of the fixed nodes are also presented in the figure. As shown by Fig. 2.1(b), initial values of $\{x_1, \dots, x_n\}$ were set by random numbers ranging from -2.5 to 2.5 by the authors, then it was able to obtain Fig. 2.1(c) and (d) by either **2-term** or **3-term method**. Fig. 2.1 (c) is the form taking minimum value of the sum of squared length of all the tension members and the corresponding minimal value was 160.214. Fig. 2.1 (d) is the form which was obtained when 4 times greater weight coefficients were assigned onto the boundary cables and the corresponding minimum value was 188.09. In both method, 0.2 was used as the step-size factor α .

Fig. 2.2 shows the history of the objective function when Fig. 2.1 (c) was obtained. As shown by Fig. 2.2, after a while α was fixed to 0.2, soon Π converged and vibrated around 160.

At that time, the norm of $|\nabla \Pi|$ was 0.13, which may be thought as not being sufficiently small. Even such cases, as shown in Fig. 2.3, it is possible to decrease $|\nabla \Pi|$ gradually by decreasing α gradually. However, this work expects the **two-term** and **three-term method** to be used as a means of exploring various equilibrium forms by varying the parameters such as weight coefficients and the coordinates of the fixed nodes freely, in which α would be kept constant such as 0.2.

Figure 2.2: History of $\Pi(\alpha = 0.2)$ (by 3-term method)

Figure 2.3: History of $|\nabla \Pi|$ (by 3-term method)

2.2. History of 3-term method

Here, it must be noted the close relation between Eq. (2.12) and the "Three-term recursion formulae". In 1959, "Three term recursion formulae" was firstly presented by M. Engeli, H. Rutishauser et. al [3]. In 1982, M. Papadrakakis stated that the dynamic relaxation method [7] and the conjugate gradient method, can be classified under the family methods with three-term recursion formulae [4]. Because Eq. (2.12) has a common form with the conjugate gradient method and its basic idea highly resemble the one of the dynamic relaxation method, it may be possible to position the **three-term method** proposed in this work as the simplest method based on the three-term recursion formulae

2.3. Direct minimization approaches with constraint conditions

Figure 2.4: Form-finding of Simplex Tensegrity

Figure 2.5: Direct Minimization Approaches under Constraint Conditions

Figure 2.6: Form-Finding of Complicate Tensegrities

In this section, direct minimization approaches with constraint conditions are discussed. As an example, let us consider the form-finding problem of a Simplex Tensegrity structure, which is shown by Fig. 2.4. A Simplex Tensegrity is a self-equilibrium structure that consist of 3 compression members which are shown as thick lines in the figure and 9 tension members, as thin lines in the figure. In addition, remark that the members are pin-jointed on only their ends.

In general, it is expected to obtain such a self-equilibrium form when some objective function with respect to the lengths of the tension members is minimized by constraining the lengths of compression members. Then, let us consider the following simple minimization problem with equally constraint conditions:

$$\begin{aligned} \Pi_w(\mathbf{x}) &= \sum_{j=1}^9 w_j L_j^4(\mathbf{x}) \rightarrow \min, \\ \text{s. t.} \quad &\begin{cases} (L_{10} - \bar{L}_{10}) = 0, \\ \vdots \\ (L_{12} - \bar{L}_{12}) = 0, \end{cases} \end{aligned} \quad (2.13)$$

where $\{L_1, \dots, L_9\}$ denote the lengths of the tension members and $\{L_{10}, \dots, L_{12}\}$ denote the lengths of the compression members. In addition, $\{w_1, \dots, w_9\}$ are the weight coefficients assigned to every tension members. Moreover, $\{\bar{L}_{10}, \dots, \bar{L}_{12}\}$ are the constraint values of the lengths of the compression members, which are treated as constant in the formulations below but are assigned with the aims of varying the form by varying them. The basis of the power 4 which is put on L_j is not explained in this work, because it has been already reported by the authors [1].

Fig. 2.4 (b) shows the form that is taking the minimum value of $\sum_j L_j^4$ when every lengths of the compression members are constrained to 10.0. The corresponding minimum value was 18000 and the methods performed by the authors are described below.

Applying the *Lagrange* multiplier method, Eq. (2.13) reduces to the following stationary problem of a functional:

$$\Pi(\mathbf{x}, \boldsymbol{\lambda}) = \sum_{j=1}^m w_j L_j^4(\mathbf{x}) + \sum_{k=1}^r \lambda_k (L_{m+k}(\mathbf{x}) - \bar{L}_{m+k}) \rightarrow \text{stationary}, \quad (2.14)$$

where the first sum is taken for all the tension members and the second sum is taken for all the compression members. In addition, $\boldsymbol{\lambda}$ is a row vector containing the multipliers $\{\lambda_1, \dots, \lambda_r\}$. From now on, let $\mathbf{x}$, $\boldsymbol{\lambda}$ and the corresponding gradient vectors be arranged as

$$\mathbf{x} \equiv [x_1 \quad \dots \quad x_n]^T, \quad \frac{\partial f}{\partial \mathbf{x}} \equiv \left[\frac{\partial f}{\partial x_1} \quad \dots \quad \frac{\partial f}{\partial x_n} \right], \quad (2.15)$$

$$\boldsymbol{\lambda} \equiv [\lambda_1 \quad \dots \quad \lambda_r], \quad \frac{\partial f}{\partial \boldsymbol{\lambda}} \equiv \left[\frac{\partial f}{\partial \lambda_1} \quad \dots \quad \frac{\partial f}{\partial \lambda_r} \right]^T. \quad (2.16)$$

Then, let the gradient operator ∇ be defined by $\nabla f \equiv \frac{\partial f}{\partial \mathbf{x}}$.

The stationary condition of Eq. (2.14) can be expressed as a set of two conditions:

$$\frac{\partial \Pi}{\partial \mathbf{x}} = \mathbf{0} \quad \& \quad \frac{\partial \Pi}{\partial \boldsymbol{\lambda}} = \mathbf{0}. \quad (2.17)$$

Thus, in this work, it is important that unknown variables $\mathbf{x}$ and multipliers $\boldsymbol{\lambda}$ are explicitly distinguished and the corresponding stationary conditions are discussed separately.

First, let us discuss the first stationary condition, namely

$$\nabla \Pi = \mathbf{0} \Leftrightarrow \sum_j 4w_j L_j^3 \nabla L_j + \sum_k \lambda_k \nabla L_k = \mathbf{0}, \quad (2.18)$$

and its general form is expressed as

$$\nabla \Pi = \nabla \Pi_w + \boldsymbol{\lambda} \cdot \mathbf{J}_\lambda = \mathbf{0}, \quad (2.19)$$

where $\nabla \Pi_w$ is the gradient of the objective function and $\mathbf{J}_\lambda$ is an Jacobian matrix given by

$$\mathbf{J}_\lambda \equiv \begin{bmatrix} \nabla L_{m+1} \\ \vdots \\ \nabla L_{m+r} \end{bmatrix}, \quad (2.20)$$

which must be refreshed in each step.

In this work, the number of the constraint conditions are assumed as being smaller than the number of the unknown variables. In addition, bad conditioned problems, such that satisfaction of the constraint conditions is almost impossible, are not discussed. The simple interpretation of above statements in terms of mathematics is that $\mathbf{J}_\lambda$ is always supposed as full-rank and the number of the columns is supposed as being greater than the one of the rows.

Taking into account the making use of the direct minimization methods on this problem, the indeterminacy of $\nabla \Pi$ must be solved, i.e. due to the unknown multipliers $\{\lambda_1, \dots, \lambda_r\}$,

$\nabla \Pi$ can not be determined uniquely, and this makes the **two-term** and the **three-term method** infeasible. In contrast, if an additional rule is supplemented with the aim of determining $\{\lambda_1, \dots, \lambda_r\}$ uniquely, $\nabla \Pi$ is also determined uniquely and both the **two-term** and the **three-term method** turn to feasible. One of the simplest ideas is making use of the Moore-Penrose type pseudo inverse matrix $\mathbf{J}_\lambda^+$.

First, Eq. (2.19) is transformed into

$$\boldsymbol{\lambda} \cdot \mathbf{J}_\lambda = -\nabla \Pi_w, \quad (2.21)$$

and then, $\boldsymbol{\lambda}$ can be determined by

$$\boldsymbol{\lambda} = -\nabla \Pi_w \cdot \mathbf{J}_\lambda^+, \quad (2.22)$$

which provides basically a least norm solution. When $\mathbf{J}_\lambda$ is supposed as fullrank, it is simply given by $\mathbf{J}_\lambda^+ = \mathbf{J}_\lambda^T \cdot (\mathbf{J}_\lambda \cdot \mathbf{J}_\lambda^T)^{-1}$. One may feel it is very hard to adopt such a least squared solution because it is not an exact solution; however, when $\mathbf{x}$ turns to a solution, $\boldsymbol{\lambda}$ given by Eq. (2.22) turns to a least norm solution and when Eq. (2.22) gives a least norm solution, it implies that a stationary point has been obtained. Otherwise, when Eq. (2.22) gives a least squared solution, it implies that $\mathbf{x}$ still has not leached to a stationary point, therefore, a supplement of an additional rule to determine $\boldsymbol{\lambda}$ uniquely must not be interfered by any reason.

As the result of above discussion, a unique mapping from $\mathbf{x}$ to $\nabla \Pi$ can be defined by

$$\nabla \Pi \equiv \nabla \Pi_w + \boldsymbol{\lambda} \cdot \mathbf{J}_\lambda = \mathbf{0} \circ (\boldsymbol{\lambda} = -\nabla \Pi_w \cdot \mathbf{J}_\lambda^+), \quad (2.23)$$

which determines a gradient vector field and thus both the **two-term** and the **three-term method** turn to feasible. The determination of $\{\nabla \Pi, \boldsymbol{\lambda}\}$ by using Eq. (2.23) is essentially identical with the **dual estimate**, which is defined in linear programming theory, particularly in the context of the primal affine scaling method [6].

By the way, the substitution appeared in Eq. (2.23) can be performed immediately, and then Eq. (2.23) reduces to

$$\nabla \Pi = \nabla \Pi_w \cdot (\mathbf{I} - \mathbf{J}_\lambda \cdot \mathbf{J}_\lambda^+), \quad (2.24)$$

which is widely known as the projected gradient in terms of the projected gradient method and in which $\boldsymbol{\lambda}$ is eliminated. However, the multipliers are always calculated explicitly in this work because the **dual estimate** can be interpreted to the **composition of forces** when $\nabla \Pi_w$ is considered as a force, $\boldsymbol{\lambda}$ as a reaction force and $\nabla \Pi$ as a resultant force as shown in Fig. 2.5 (a).

Let us recall and discuss the second stationary condition, namely

$$\frac{\partial \Pi}{\partial \boldsymbol{\lambda}} = \mathbf{0} \Leftrightarrow \begin{cases} (L_{m+1} - \bar{L}_{m+1}) = 0 \\ \vdots \\ (L_{m+r} - \bar{L}_{m+r}) = 0 \end{cases}, \quad (2.25)$$

which is apparently the prescribed equally constraint conditions themselves. One of the simplest ideas to satisfy Eq. (2.25) is to solve simultaneous linear equations such as

$$\mathbf{J}_\lambda \cdot \Delta \mathbf{x} = -\mathbf{r}, \quad (2.26)$$

where $\Delta \mathbf{x}$ is a correction vector of $\mathbf{x}$ and $\mathbf{r}$ is a residual vector given by

$$\mathbf{r} = \begin{bmatrix} L_{m+1}(\mathbf{x}) - \bar{L}_{m+1} \\ \vdots \\ L_{m+r}(\mathbf{x}) - \bar{L}_{m+r} \end{bmatrix}. \quad (2.27)$$

The definition of $\mathbf{J}_\lambda$ is apparently identical with Eq. (2.20), but should be refreshed again. Here, the Moore-Penrose type pseudo inverse $\mathbf{J}_\lambda^+$ plays an important role again to determine $\Delta \mathbf{x}$ as

$$\Delta \mathbf{x} = -\mathbf{J}_\lambda^+ \cdot \mathbf{r}, \quad (2.28)$$

which basically gives a least norm solution. In addition, because $\mathbf{x}$ can places far from the hyper-surface on which the constraint conditions are satisfied, it is highly recommended to rescale $\Delta \mathbf{x}$ to prevent the computation being unstable, such as

$$\mathbf{x}_{\text{Current}} := \mathbf{x}_{\text{Current}} + 0.5\Delta \mathbf{x}, \quad (2.29)$$

where $:$ symbol represents a substitution of the right hand side into left hand side. If Eq. (2.29) is always performed once after the execution of Eq. (2.11) or Eq. (2.12) in each step, $\mathbf{x}$ would gradually approaches to the hyper-surface on which the prescribed constraint conditions are satisfied and soon, the motion of $\mathbf{x}$ generated by the **two-term** or the **three-term method** will be constrained onto such a hyper-surface, as shown by Fig. 2.5(b). By using either **two-term** or **three-term method**, Fig. 2.4 (b) was obtained. By introducing Eq. (2.29), it is also enabled starting the computation from random numbers. As same as in the previous section, to obtain Fig. 2.4 (b), the authors gave random numbers ranging from -2.5 to 2.5 to the initial values of $\{x_1, \dots, x_n\}$ and set the step-size factor α as 0.2.

By comparing Eq. (2.24) and Eq. (2.28), one may notice that $\nabla \Pi$ and $\Delta \mathbf{x}$ are row and column vectors which are selected from completely decomposed two spaces that are orthogonal to each other, because $(\mathbf{I} - \mathbf{J}_\lambda^+ \cdot \mathbf{J}_\lambda)$ represents the kernel of $\mathbf{J}_\lambda^+$ and vice versa. As is depicted in Fig. 2.5 (b), the n -dimensional search space (usually assumed as an Euclidean space) that $\mathbf{x}$ belongs to is firstly decomposed into a group of hyper-surfaces on which residual vector $\mathbf{r}$ taking the same value. Then, on each point of each hyper-surface, the vector space attached to each point is completely decomposed into the tangent subspace and the orthogonal complement. Finally, each of $\nabla \Pi$ and $\Delta \mathbf{x}$ is selected from each of the tangent subspace and the orthogonal complement respectively. Thus, the feature of the method proposed in this work which should be emphasized is that two subspaces that are orthogonal to each other correspond to two separated stationary conditions, and, two different strategies are performed independently on each subspace.

By the way, when minimization problems with constraint conditions are solved by the method proposed above, the **two-term method** become sometimes useless, particularly on complicate problems. In contrast, by using the **three-term method**, it was still possible to find the forms of complicate structures such as the tensegrities shown by Fig. 2.6 (see [1]).

Such complicate problem on which the **three-term method** works better than the **two-term method** can be easily found widely. Fig. 2.7 shows such another form-finding analysis, in which, the analytical model consists of cables, membranes, compression members and fixed points, and based on the famous Tanzbrunnen in Cologne AïFrei Otto, 1959Aj. The selected stationary problem that was solved is as follows:

$$\begin{aligned} \Pi(\mathbf{x}, \lambda) = & \sum_{j=1}^m w_j L_j^4(\mathbf{x}) + \sum_k w_k S_k^2(\mathbf{x}) \\ & + \sum_{l=1}^r \lambda_l (L_{m+l}(\mathbf{x}) - \bar{L}_{m+l}) \rightarrow \text{stationary}, \end{aligned} \quad (2.30)$$

where the cables, the membranes are subdivided into line elements and triangle elements, and the first sum is taken for all the line elements and the second sum is taken for all the triangle elements. In addition, the third sum is taken for all the compression members, which can be composed into a stationary problem by applying the *Lagrange* multiplier method to the constraint conditions. Moreover, L_j , S_k , and L_{m+l} are the functions that respectively represent the length of a line element, the area of a triangle element, and the length of a compression member.

The statinoary condition with respect to $\mathbf{x}$ can be expressed as :

$$\nabla \Pi = \sum_j^m 4w_j L_j^3 \nabla L_j + \sum_k 2w_k S_k \nabla S_k + \sum_l^r \lambda_l \nabla L_{m+l} = \mathbf{0}, \quad (2.31)$$

and then, taking the inner-product between $\delta \mathbf{x}$ and Eq. (2.31), the **principle of virtual work** for this problem can be expressed as:

$$\delta w = \sum_j^m 4w_j L_j^3 \delta L_j + \sum_k 2w_k S_k \delta S_k + \sum_l^r \lambda_l \delta L_{m+l} = 0. \quad (2.32)$$

As means of solving Eq. (2.30), while **two-term method** was completely useless, the **three-term method** worked really fine. What is more important is that it was also possible to vary the form by varying the weight coefficients or the lengths of the compression members and to explore the possible self-equilibrium forms.

On the basis of above considerations, this research is strongly focused on the **three-term method**, even though the **two-term method**, or the steepest decent method, is sometimes described as one of the most standard direct minimization methods. In the next section, the formulations for solving various types of static problems of continuum bodies by the **three-term method** are presented.

3. Continuum mechanics

When the gradient of the volume of a tetrahedron element, ∇V_j , is added to a set of ∇L_j and ∇S_j , a compact framework

Figure 2.7: Form-Finding of Tanzbrunnen in Cologne (F. Otto, 1959)

in which a set of $\{\nabla L_j, \nabla S_j, \nabla V_j\}$ is adopted as basic gradient vectors can be formed; however, this framework is almost useless, because, while the stress tensor defined on a 3-dimensional body usually has 6 degree of freedom, the degree of freedom that ∇V_j has is at most only the scalar multiplication. Hence, a further consideration on the continuum mechanics must be needed, if taking into account the **three-term method** on solving various types of static problems of continuum mechanics. In this section, the discrete **principle of virtual work**, the **stationary condition**, the **standard search direction** are derived from the **principle of virtual work** that is a governing field equation. Additionally, a general form of $\{\nabla L_j, \nabla S_j, \nabla V_j\}$ is presented as $\omega_j^N(T_{\cdot k}^i)$.

3.1. Minimal surfaces and uniform stress surfaces

From now on, *Einstein* summation convention is used. In this subsection, the relation between minimal surfaces and the uniform stress surfaces are discussed. A minimal surface is a surface such that when its form is varied arbitrarily by fixing its boundary, its surface area does not change.

In general, the surface area of a surface having a fixed boundary can be expressed as:

$$a \equiv \int_a da, \quad da \equiv \sqrt{\det g_{ij}} d\theta^1 d\theta^2 \quad (1 \leq i, j \leq 2), \quad (3.1)$$

where g_{ij} , θ^1 , θ^2 represents the *Riemannian* metric and the local coordinate parameters which are defined on each point of the surface. Then, the variation of surface area can be expressed as:

$$\delta a = \int_a \delta \sqrt{\det g_{ij}} d\theta^1 d\theta^2. \quad (3.2)$$

Here, it is widely known that $\delta \sqrt{\det g_{ij}}$ can be expanded as

$$\delta \sqrt{\det g_{ij}} = \frac{1}{2} g^{ij} \delta g_{ij}, \quad (3.3)$$

where g^{ij} is defined as the inverse of g_{ij} , namely $g^{ij} = (g_{ij})^{-1}$. Additionally, δg_{ij} is not completely arbitrary but must be geometrically admissible, namely δg_{ij} must be expressed as

$$\delta g_{ij} = (\nabla_i \delta u^k) g_{kj} + (\nabla_j \delta u^k) g_{ki} - 2h_{ij} \delta u^3, \quad (3.4)$$

where $\{\delta u^1, \delta u^2, \delta u^3\}$ are arbitrary scalar fields such that each δu^k satisfies $\delta u^k = 0$ on the boundary; however the detail of Eq. (3.4) is not discussed in this work because what is only needed for the **three-term method** is just an approximation of δg_{ij} and not δg_{ij} itself. While Eq. (3.4) is a field equation, the aim of this work is to avoid such complicate and difficult field equations and to obtain an approximated solution easily by the direct minimization methods.

Substituting Eq. (3.3) into Eq. (3.2), the **minimal surface problem** can be expressed as:

$$\delta a = 0 \Leftrightarrow \frac{1}{2} \int_a g^{ij} \delta g_{ij} da = 0. \quad (3.5)$$

Eq. (3.5) has a close relation with the **principle of virtual work** of self-equilibrium membranes whose boundary is fixed:

$$\delta w = \frac{1}{2} \int_a t \sigma^{ij} \delta g_{ij} da = 0 \quad (1 \leq i, j \leq 2), \quad (3.6)$$

where t and σ^{ij} respectively denote the thickness and the Cauchy stress tensor defined on each point of the surface. Additionally, $\frac{1}{2} \delta g_{ij}$ is used instead of the variation of strain due to the essential identity between them.

Using raising and lowering indices law of tensors, i.e. $X^{ij} = X_{\cdot k}^i g^{kj}$, the **principle of virtual work** is transformed into:

$$\delta w = \frac{1}{2} \int_a t \sigma_{\cdot k}^i g^{kj} \delta g_{ij} da = 0 \quad (1 \leq i, j, k \leq 2). \quad (3.7)$$

Moreover, when a new stress tensor $T_{\cdot k}^i$ is defined by

$$T_{\cdot k}^i \equiv t \sigma_{\cdot k}^i, \quad (3.8)$$

Eq. (3.7) is transformed again into:

$$\delta w = \frac{1}{2} \int_a T_{,k}^i g^{kj} \delta g_{ij} da = 0 \quad (1 \leq i, j, k \leq 2). \quad (3.9)$$

On the other hand, Eq. (3.5), the **minimal surface problem** is also transformed into:

$$\delta a = \frac{1}{2} \int_a \delta_{,j}^i g^{kj} \delta g_{ij} da = 0 \quad (1 \leq i, j, k \leq 2), \quad (3.10)$$

which can be a simple demonstration of the essential identity between minimal surfaces and uniform stress surfaces.

3.2. Principle of virtual work for N -Dimensional Riemannian manifolds

In this subsection, the formulations appeared in the previous subsection are generalized into any dimensional spaces from 2-dimensional spaces (surfaces). The length, the area, and the volume of a curve, a surface, and a body which have a boundary are expressed as:

$$l \equiv \int_l dl, \quad a \equiv \int_a da, \quad v \equiv \int_v dv, \quad (3.11)$$

where dl , da , dv are respectively called the line element, the surface element, and the volume element which are defined by

$$dl \equiv \sqrt{g_{11}} d\theta^1, \quad (3.12)$$

$$da \equiv \sqrt{\det g_{ij}} d\theta^1 d\theta^2 \quad (1 \leq i, j \leq 2), \quad (3.13)$$

$$dv \equiv \sqrt{\det g_{ij}} d\theta^1 d\theta^2 d\theta^3 \quad (1 \leq i, j \leq 3), \quad (3.14)$$

where g_{ij} represent the *Riemannian* metrics defined on each point of each geometry. Such geometries on which *Riemannian* metric is defined on each point, can be classified as 1,2,3-dimensional *Riemannian* manifold.

Noticing the common forms appeared in Eq. (3.11), (3.12), (3.13), (3.14), it is very natural to define the volume element and the volumen of a N -dimensional *Riemannian* manifold M by

$$dv^N \equiv \sqrt{\det g_{ij}} d\theta^1 \cdots d\theta^N, \quad v^N \equiv \int_M dv^N, \quad (3.15)$$

then the variation of the volume of M can be expressed by

$$\delta v^N = \frac{1}{2} \int_M g^{ij} \delta g_{ij} dv^N. \quad (3.16)$$

Hence, the **minimal volume problem** of M can be defined by:

$$\delta v^N = \frac{1}{2} \int_M g^{ij} \delta g_{ij} dv^N = 0 \quad (1 \leq i, j \leq N). \quad (3.17)$$

By the way, the self-equilibrium equations of cables, membranes, and 3-dimensional bodies whose boundary is fixed can be expressed in the form of the **principle of virtual work** as follows:

$$\delta w^1 = \frac{1}{2} \int_l A \sigma_{,k}^i g^{kj} \delta g_{ij} dl = 0 \quad (i, j, k = 1), \quad (3.18)$$

$$\delta w^2 = \frac{1}{2} \int_a t \sigma_{,k}^i g^{kj} \delta g_{ij} da = 0 \quad (1 \leq i, j, k \leq 2), \quad (3.19)$$

$$\delta w^3 = \frac{1}{2} \int_v \sigma_{,k}^i g^{kj} \delta g_{ij} dv = 0 \quad (1 \leq i, j, k \leq 3), \quad (3.20)$$

where t and A respectively denote the sectional area of a cable and the thickness of a membrane.

Here, when new stress tensor $T_{,k}^i$ is defined for each dimension individually as:

$$T_{,k}^i \equiv A \sigma_{,k}^i \quad (N = 1), \quad T_{,k}^i \equiv t \sigma_{,k}^i \quad (N = 2), \quad \text{and} \quad T_{,k}^i = \sigma_{,k}^i \quad (N = 3), \quad (3.21)$$

Eq. (3.18), Eq. (3.17) and Eq. (3.20) are unified into:

$$\delta w^N = \frac{1}{2} \int_M T_{,k}^i g^{kj} \delta g_{ij} dv^N = 0 \quad (1 \leq i, j, k \leq N), \quad (3.22)$$

which is the **principle of virtual work** for self-equilibrium N -dimensional *Riemannian* manifold M .

Here, Eq. (3.17), the **minimal volume problem** of M , can be transformed into:

$$\delta v^N = \frac{1}{2} \int_M \delta_{,j}^i g^{kj} \delta g_{ij} dv^N = 0 \quad (1 \leq i, j, k \leq N). \quad (3.23)$$

By comparing Eq. (3.22) and Eq. (3.23), it can be noticed that the **minimal volume problem** is a special cases of the **principle of virtual work** such that $T_{,k}^i = \delta_{,k}^i$, and the **principle of virtual work** is one of the natural generalizations of the **minimal volume problem**. In general, $\delta_{,k}^i$ can be classed with the unit matrix.

3.3. Galerkin method

The **principle of virtual work** which is defined in the previous sub section, i.e.

$$\delta w = \frac{1}{2} \int_M T_{,k}^i g^{kj} \delta g_{ij} dv^N = 0 \quad (3.24)$$

is basically a field equation; namely the degree of freedom of δg_{ij} is infinite. Then, with the aim of solving the **principle of virtual work** by the direct minimization methods, in this subsection, discrete **principle of virtual work** is deduced.

First, when the form is explicitly represented by n independent parameters such as $\{x_1, \dots, x_n\}$, then $\mathbf{x}$, $\delta \mathbf{x}$, and $\nabla f = \frac{\partial f}{\partial \mathbf{x}}$ can be defined with the same manner of section 2. When, the degree of freedom of the form is n , then at most n independent δg_{ij} can satisfy Eq. (3.24). Thus, in general, any form on which n independent δg_{ij} can satisfy Eq. (3.24) is usually adopted as an approximated solution. One of such natural ways of giving δg_{ij} is altering δg_{ij} into

$$\delta \tilde{g}_{ij} = \nabla g_{ij} \cdot \delta \mathbf{x}, \quad (3.25)$$

which is essentially the *Galerkin* method. If δg_{ij} is altered into Eq. (3.25), the discrete **principle of virtual work** (weak form) is obtained as:

$$\delta w^N = \frac{1}{2} \int_M T_{,k}^i g^{kj} (\nabla g_{ij} \cdot \delta \mathbf{x}) dv^N = 0, \quad (3.26)$$

then, letting $\delta \mathbf{x}$ out of the integral operator, discrete **principle of virtual work** (strong form) is obtained as:

$$\Leftrightarrow \left(\frac{1}{2} \int_M T_{,k}^i g^{kj} \nabla g_{ij} dv^N \right) \cdot \delta \mathbf{x} = 0, \quad (3.27)$$

finally, due to the arbitrariness of $\delta \mathbf{x}$,

$$\Leftrightarrow \omega = \frac{1}{2} \int_M T_{,k}^i g^{kj} \nabla g_{ij} dv^N = \mathbf{0}, \quad (3.28)$$

which is the discrete **stationary condition** and can be also positioned as a discrete form of a self-equilibrium equation.

When external forces are acting on the manifold M , the discrete **principle of virtual work** (strong form) is firstly expressed as

$$\left(\frac{1}{2} \int_M T_{,k}^i g^{kj} \nabla g_{ij} dv^N \right) \cdot \delta \mathbf{x} = \mathbf{p} \cdot \delta \mathbf{x}, \quad (3.29)$$

and it follows

$$\Leftrightarrow \omega = \frac{1}{2} \int_M T_{,k}^i g^{kj} \nabla g_{ij} dv^N - \mathbf{p} = \mathbf{0}, \quad (3.30)$$

where $\mathbf{p}$ is a row vector containing the components of the nodal loads, which should be basically derived via some discretization process of continuum load but further detail is not discussed in this work because it has been already discussed in the usual finite element formulations.

Then, since the discrete **stationary condition** is an n -order simultaneous non-linear equations and the number of the unknown variables is n so that basically it can be solved. In addition, when the discrete **stationary condition** is solved by the direct minimization methods,

$$\mathbf{r} = \frac{\omega^T}{|\omega|}, \quad (3.31)$$

is adopted as the **standard search direction**.

3.4. N -dimensional Simplex elements

The discrete stationary condition $\omega = \mathbf{0}$ which is derived in the previous subsection still contains integral operator, which is the last obstacle to be overcome. In this subsection, as a powerful means of calculating ω on general numerical environment, N -dimensional Simplex element is presented.

When the integral domain is subdivided into m elements, if element integral is defined by

$$\omega_j^N(T_{,\gamma}^\alpha) \equiv \frac{1}{2} \int_j T_{,\gamma}^\alpha g^{\gamma\beta} \nabla g_{\alpha\beta} dv^N, \quad (3.32)$$

where the integral operation is calculated separately within each element, then, ω can be simply expressed as

$$\omega = \sum_j \omega_j^N \text{ or } \omega = \sum_j \omega_j^N - \mathbf{p}. \quad (3.33)$$

The most simplest idea to calculate Eq. (3.32) is to let the integrated function constant within each element. Fig. (3.1) shows

1,2,3-dimensional Simplex elements, which are apparently just the line, triangle, and tetrahedron element having $N + 1$ nodes.

From now on, first, let $\{\mathbf{p}_1, \dots, \mathbf{p}_{N+1}\}$ be a set of the Cartesian coordinates of the nodes of an element, and then second, let $\{\theta^1, \dots, \theta^N\}$ be a simple local coordinate defined on the element. Third, let each coordinate parameter be taking the value from 0 to 1. Then, finally, the global coordinate (assumed as the Cartesian coordinate) of each point within the element can be given by an interpolation function defined by

$$\mathbf{r}(\theta^1, \dots, \theta^N) = \theta^1 (\mathbf{p}_1 - \mathbf{p}_2) + \dots + \theta^N (\mathbf{p}_N - \mathbf{p}_{N+1}) + \mathbf{p}_{N+1}. \quad (3.34)$$

Then, referring to the definition of the base vectors, namely

$$\mathbf{g}_i \equiv \frac{\partial \mathbf{r}}{\partial \theta^i}, \quad (3.35)$$

$\mathbf{g}_1 \dots \mathbf{g}_N$ can be calculated by

$$\mathbf{g}_i = \mathbf{p}_i - \mathbf{p}_{i+1} \quad (1 \leq i \leq N), \quad (3.36)$$

which is apparently constant within the element. Hence, the *Riemannian metric*

$$g_{ij} = \mathbf{g}_i \cdot \mathbf{g}_j \quad (3.37)$$

is also constant within the element. Moreover, when considering the usual elastic bodies, $T_{,k}^i$ is usually dependent on only g_{ij} , then $T_{,k}^i$ is also constant within the element. As the result of above considerations, the integrated function is constant within the element and the following formulations can be used:

$$\omega_j^1(T_{,\gamma}^\alpha) \equiv \frac{1}{2} L_j [T_{,\gamma}^\alpha g^{11} \nabla g_{11}]_j, \quad (3.38)$$

$$\omega_j^2(T_{,\gamma}^\alpha) \equiv \frac{1}{2} S_j [T_{,\gamma}^\alpha g^{\gamma\beta} \nabla g_{\alpha\beta}]_j \quad (1 \leq \alpha, \beta, \gamma \leq 2), \quad (3.39)$$

$$\omega_j^3(T_{,\gamma}^\alpha) \equiv \frac{1}{2} V_j [T_{,\gamma}^\alpha g^{\gamma\beta} \nabla g_{\alpha\beta}]_j \quad (1 \leq \alpha, \beta, \gamma \leq 3), \quad (3.40)$$

where L_j, S_j, V_j respectively denote the length, the area, and the volume of each dimensional element, namely they are given by

$$L_j = \sqrt{\det g_{11}}_j, \quad (3.41)$$

$$S_j = \frac{1}{2} \sqrt{\det g_{\alpha\beta}}_j \quad (1 \leq \alpha, \beta \leq 2), \quad (3.42)$$

$$V_j = \frac{1}{6} \sqrt{\det g_{\alpha\beta}}_j \quad (1 \leq \alpha, \beta \leq 3). \quad (3.43)$$

In addition, g^{ij} is the inverse of g_{ij} . The inverses of tiny matrices can be calculated by using the following explicit representations:

$$(g_{11})^{-1} = \frac{1}{g_{11}}, \quad (3.44)$$

$$\begin{bmatrix} g_{11} & g_{12} \\ g_{21} & g_{22} \end{bmatrix}^{-1} = \frac{1}{\det g_{ij}} \begin{bmatrix} g_{22} & -g_{12} \\ -g_{21} & g_{11} \end{bmatrix}, \quad (3.45)$$

Figure 3.1: Simplex Elements

$$\begin{bmatrix} g_{11} & g_{12} & g_{13} \\ g_{21} & g_{22} & g_{23} \\ g_{31} & g_{32} & g_{33} \end{bmatrix}^{-1} = \frac{1}{\det g_{ij}} \left[\begin{bmatrix} g_{12} \\ g_{22} \\ g_{32} \end{bmatrix} \times \begin{bmatrix} g_{13} \\ g_{23} \\ g_{33} \end{bmatrix} \right] \quad (3.46)$$

$$\left[\begin{bmatrix} g_{13} \\ g_{23} \\ g_{33} \end{bmatrix} \times \begin{bmatrix} g_{11} \\ g_{21} \\ g_{31} \end{bmatrix} \right] \times \begin{bmatrix} g_{12} \\ g_{22} \\ g_{32} \end{bmatrix} \right], \quad (3.47)$$

where

$$\begin{bmatrix} a_1 \\ a_2 \\ a_3 \end{bmatrix} \times \begin{bmatrix} b_1 \\ b_2 \\ b_3 \end{bmatrix} \equiv \begin{bmatrix} a_2 b_3 - b_2 a_3 \\ a_3 b_1 - b_3 a_1 \\ a_1 b_2 - b_1 a_2 \end{bmatrix}. \quad (3.48)$$

Thus, the tiny inverses have been completely eliminated from ω .

3.5. Gradient vectors and the general form

Figure 3.2: $\omega_j^N (T_k^i = \delta_k^i)$

In this subsection, the relation between $\omega_j^N (T_\gamma^\alpha)$ and the gradient vectors are discussed.

Interestingly, as are depicted in Fig. 3.2, when $T_\gamma^\alpha = \delta_\gamma^\alpha$, the following exact relations are formed:

$$\omega_j^1 (\delta_\gamma^\alpha) = \nabla L_j, \quad (3.49)$$

$$\omega_j^2 (\delta_\gamma^\alpha) = \nabla S_j, \quad (3.50)$$

$$\omega_j^3 (\delta_\gamma^\alpha) = \nabla V_j. \quad (3.51)$$

The demonstrations of above relations can be obtained by altering δ symbols into ∇ symbols in the demonstration of that the **minimal volume problem** is a special case of the **principle of virtual work** such that $T_\gamma^\alpha = \delta_\gamma^\alpha$, which was described in the subsection 3.2. Therefore, a set of $\{\nabla L_j, \nabla S_j, \nabla V_j\}$ coincides

with $\{\omega_j^1 (T_\gamma^\alpha), \omega_j^2 (T_\gamma^\alpha), \omega_j^3 (T_\gamma^\alpha)\}$ when $T_\gamma^\alpha = \delta_\gamma^\alpha$, and then $\omega_j^N (T_\gamma^\alpha)$ is one of the natural generalizations of $\{\nabla L_j, \nabla S_j, \nabla V_j\}$. Furthermore, $\omega_j^N (T_\gamma^\alpha)$ can be used when $\{\nabla L_j, \nabla S_j, \nabla V_j\}$ are calculated.

Based on above considerations, it can be noticed that only special cases such that T_γ^α is given as just a scalar multiple of δ_γ^α have been discussed in the section 2. Therefore, it is very natural to consider general functions as T_γ^α . Particularly, a map from g_{ij} to T_γ^α is no other than the constitutive law itself.

The explicit representations of ∇L_j and ∇S_j are presented in Appendix A and one may notice that they look very different while the difference between ω_j^1 and ω_j^2 is just the dimensions of the matrices; however, due to g^{ij} which is defined as inverse matrix, the apparent difference between ∇L_j and ∇S_j is resulted from the difference between the explicit representations of tiny inverse matrices.

By the way, each ω_j^N is just a mixture of the gradient vectors ∇g_{ij} , then even though a function f_j such that $\omega_j^N = \nabla f_j$, is not found in usual, ω_j^N is a row vector that highly resemble the gradient vectors. Therefore, the **discrete stationary condition** which was formulated in the subsection 3.3 is expected to be solved by the **two-term** or the **three-term method** by just altering $\nabla \Pi$ into ω .

3.6. Numerical examples

In this subsection, some examples that discrete **stationary conditions** can be solved by the **three-term method** are illustrated. As the simplest constitutive law, only

$$T_k^i = E g^{il} (g_{lk} - \bar{g}_{lk}), \quad (3.52)$$

$$\therefore T^{ij} = T_k^i g^{kj} = E g^{il} (g_{lk} - \bar{g}_{lk}) g^{kj}, \quad (3.53)$$

is considered, which is the uniform linear material with Poisson ratio=0, and where E is the stiffness factor. It must be remarked that the stiffness factor E is identical with Young's modulus only when $N = 3$, otherwise it is multiplied with the sectional area or the thickness, when a *Riemannian* manifold is related with a real material. Additionally, $e_{ik} = (g_{ik} - \bar{g}_{ik})$ is no other than the strain tensor itself and $\bar{g}_{ik}$ is the *Riemannian* metric treated as constant and is measured on the initial shape on which

the stress tensor vanishes. Note that while $T_{.k}^i$ is not a symmetric matrix, T^{ij} is a symmetric matrix.

Unlike the numerical examples described in the section 2, in each initial step of the following numerical examples, $\{x_1, \dots, x_n\}$ were not given by random numbers but were given by the coordinates of the initial shape, and $\bar{g}_{ik}$ were calculated on such initial shapes.

Fig. 3.3 and 3.4 show natural forms of handkerchief that are hanged by 1, or 2 point under gravity. The dimension of the numerical model is 8.0×8.0 , and every z-components of the nodal forces were set as 0.1. Each form has been obtained by solving

$$\omega = \sum_j \omega_j^2 (T_{.k}^i) - p = 0, \quad (3.54)$$

which is a **discrete stationary condition** or a discrete form of equilibrium equation, by the **three-term method**. In addition, $E = 50$ as the stiffness factor and $\alpha = 0.2$ as the step-size factor were used.

Figure 3.3: Natural Forms of Handkerchief 1

Figure 3.4: Natural Forms of Handkerchief 2

Fig. 3.5 shows the large deformations of a cantilever under gravity whose dimension is $2.0 \times 2.0 \times 12.0$. Fig. 3.6 shows the large deformations after buckling of a bar which has the same dimension of the former. Each form has been obtained by solving

$$\omega = \sum_j \omega_j^3 (T_{.k}^i) - p = 0, \quad (3.55)$$

which is the **discrete stationary condition**, by the **three-term method**. In both analyses, $E = 50$ as the stiffness factor and $\alpha = 0.2$ as the step-size factor were used.

In the analysis which resulted Fig. 3.5, every z-components of the nodal forces were set as p , which is shown in the figure. In the analysis which resulted Fig. 3.6, small random numbers were firstly supplemented to the initial nodal coordinates to make the model easily buckle. Then, z-components of the nodal forces of only 9 nodes which place on the top of the model were set as p , which is shown in the figure. Even if this can be explained as one kind of buckling phenomena, the analysis itself is just a large deformation analysis; hence precise identify of critical load is almost impossible. However, the Euler buckling load corresponding to this example was calculated as $p_{cr} = 1.14$ and its division by 9 is 0.126, which indeed places between Fig. 3.6 (a) and (b).

Figure 3.5: Large deformations of a cantilever under gravity

Figure 3.6: Large deformation after buckling

4. Conclusions

In the first half of this work, the direct minimization approaches were discussed, in which some form finding problems of tension structures were considered. Especially, as the standard strategies of for direct minimization approaches, the **two-term method**, the **three-term method**, and the **dual estimate** were presented. In addition, the relation over the **principle of virtual work**, the **stationary condition**, and the **standard search direction** were clarified, which are the means of direct minimization approaches.

In the last half of this work, starting from the **principle of virtual work** (field equation) that usually appeared in the continuum mechanics, the discrete **principle of virtual work** was deduced. Moreover, the the discrete **stationary condition** and the **standard search direction** were formulated to let the **three-term method** feasible. Those formulae were expressed

with $\omega_j^N(T_k^i)$, which is one of the natural generalizations of $\{\nabla L_j, \nabla S_j, \nabla V_j\}$, hence, the last half of this work was a generalization of the first half of this work. Finally, some large deformation analyses of continuum bodies were illustrated. Those various types of numerical examples which were shown in this work imply the potential ability of the **three-term method** that can be a powerful means of solving various types of static problems of continuum bodies.

Appendix A. Gradients

Appendix A.1. Gradient of Linear Element Length

Suppose p and q denote two nodes. Let

$$\mathbf{p} \equiv \begin{bmatrix} p_x \\ p_y \\ p_z \end{bmatrix} \text{ and } \mathbf{q} \equiv \begin{bmatrix} q_x \\ q_y \\ q_z \end{bmatrix} \quad (\text{A.1})$$

represent the Cartesian coordinates of p and q.

The length of the line determined by p and q is given by

$$L(p_x, p_y, p_z, q_x, q_y, q_z) \quad (\text{A.2})$$

$$\equiv \sqrt{(p_x - q_x)^2 + (p_y - q_y)^2 + (p_z - q_z)^2}. \quad (\text{A.3})$$

If the gradient of L is defined by

$$\hat{\nabla} L \equiv \left[\frac{\partial L}{\partial p_x}, \frac{\partial L}{\partial p_y}, \frac{\partial L}{\partial p_z}, \frac{\partial L}{\partial q_x}, \frac{\partial L}{\partial q_y}, \frac{\partial L}{\partial q_z} \right], \quad (\text{A.4})$$

its components are as follows:

$$\hat{\nabla} L = \left[\frac{p_x - q_x}{L}, \frac{p_y - q_y}{L}, \frac{p_z - q_z}{L}, \frac{q_x - p_x}{L}, \frac{q_y - p_y}{L}, \frac{q_z - p_z}{L} \right], \quad (\text{A.5})$$

and its visualization is presented by Fig. A.1.

Let us investigate δL , i.e.

$$\delta L \equiv \hat{\nabla} L \cdot \begin{bmatrix} \delta \mathbf{p} \\ \delta \mathbf{q} \end{bmatrix}. \quad (\text{A.6})$$

As shown in Fig. A.2, $\delta \mathbf{p}$ and $\delta \mathbf{q}$ are firstly projected to the line determined by p and q, then, δL is measured on the line.

Figure A.1: $\hat{\nabla} L_j$

Figure A.2: Variation of Element Length

Appendix A.2. Gradient of Triangular Element Area

Let p, q, and r be three vertices. Let

$$\mathbf{p} \equiv \begin{bmatrix} p_x \\ p_y \\ p_z \end{bmatrix}, \mathbf{q} \equiv \begin{bmatrix} q_x \\ q_y \\ q_z \end{bmatrix}, \mathbf{r} \equiv \begin{bmatrix} r_x \\ r_y \\ r_z \end{bmatrix}, \quad (\text{A.7})$$

denote the Cartesian coordinates of p, q, and r.

The area of the triangle determined by p, q, and r is given by

$$S(p_x, \dots, r_z) \equiv \frac{1}{2} \sqrt{\mathbf{N} \cdot \mathbf{N}}, \quad (\text{A.8})$$

$$(\mathbf{N} \equiv (\mathbf{q} - \mathbf{p}) \times (\mathbf{r} - \mathbf{p})). \quad (\text{A.9})$$

If the gradient of S is defined by

$$\hat{\nabla} S \equiv \left[\frac{\partial S}{\partial p_x}, \frac{\partial S}{\partial p_y}, \frac{\partial S}{\partial p_z}, \dots, \frac{\partial S}{\partial r_z} \right], \quad (\text{A.10})$$

its components are as follows:

$$\begin{aligned}\hat{\nabla}S = \frac{1}{2}\mathbf{n} \cdot & \left\{ (\mathbf{r}-\mathbf{q}) \times \left[\begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix}, \begin{bmatrix} 0 \\ 1 \\ 0 \end{bmatrix}, \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix} \right] \right. \\ & \cdot (\mathbf{p}-\mathbf{r}) \times \left[\begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix}, \begin{bmatrix} 0 \\ 1 \\ 0 \end{bmatrix}, \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix} \right] \\ & \left. \cdot (\mathbf{q}-\mathbf{p}) \times \left[\begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix}, \begin{bmatrix} 0 \\ 1 \\ 0 \end{bmatrix}, \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix} \right] \right\},\end{aligned}\quad (\text{A.11})$$

where $\mathbf{n}$ is defined by

$$\mathbf{n} \equiv \frac{\mathbf{N}}{|\mathbf{N}|}, \quad (\text{A.12})$$

and a visualization of $\hat{\nabla}S$ is presented by Fig. A.3.

Let us investigate δS , i.e.

$$\delta S = \frac{1}{2}\mathbf{n} \cdot ((\mathbf{r}-\mathbf{q}) \times \delta\mathbf{p} + (\mathbf{p}-\mathbf{r}) \times \delta\mathbf{q} + (\mathbf{q}-\mathbf{p}) \times \delta\mathbf{r}). \quad (\text{A.13})$$

With respect to $\delta\mathbf{p}$, for example, when $\delta\mathbf{p}$ is orthogonal to the element, $(\mathbf{r}-\mathbf{q}) \times \delta\mathbf{p}$ becomes orthogonal to $\mathbf{n}$, then δS vanishes (see Fig. A.4). On the other hand, when $\delta\mathbf{p}$ is parallel to the opposite side, $(\mathbf{r}-\mathbf{q}) \times \delta\mathbf{p}$ vanishes, then δS vanishes. Therefore, only the component of $\delta\mathbf{p}$ which is parallel to the perpendicular line from p to the opposite side can produce δS . In other words, δS is measured on the plane determined by p, q, and r.

Figure A.3: $\hat{\nabla}S_j$

Figure A.4: Variation of Element Area

which can be expanded as

$$\begin{aligned}dg_{ij} = & dX_{i+1}(X_{j+1} - X_j) - dX_i(X_{j+1} - X_j) + dX_{j+1}(X_{i+1} - X_i) - dX_j(X_{i+1} - X_i) \\ & + dY_{i+1}(Y_{j+1} - Y_j) - dY_i(Y_{j+1} - Y_j) + dY_{j+1}(Y_{i+1} - Y_i) - dY_j(Y_{i+1} - Y_i) \\ & + dZ_{i+1}(Z_{j+1} - Z_j) - dZ_i(Z_{j+1} - Z_j) + dZ_{j+1}(Z_{i+1} - Z_i) - dZ_j(Z_{i+1} - Z_i),\end{aligned}\quad (\text{A.15})$$

where $\{X_i, Y_i, Z_i\}$ ($1 \leq i \leq N+1$) represents the Cartesian coordinates of i -th node.

When the independent parameters $\{x_1, \dots, x_n\}$ are selected as the Cartesian coordinates of all the free nodes $\{X_i, Y_i, Z_i\}$ ($1 \leq i \leq N+1$), by comparing Eq. (A.15) and the following relation, the explicit representation of ∇g_{ij} can be obtained.

$$dg_{ij} = \left[\frac{\partial g_{ij}}{\partial x_1} \dots \frac{\partial g_{ij}}{\partial x_n} \right] \begin{bmatrix} dx_1 \\ \vdots \\ dx_n \end{bmatrix} = \nabla g_{ij} \cdot \begin{bmatrix} dx_1 \\ \vdots \\ dx_n \end{bmatrix}. \quad (\text{A.16})$$

Appendix A.3. Gradient of Riemannian Metrics

The explicit representation of ∇g_{ij} can be obtained by referring the following calculations. First, Eq. (3.35) and Eq. (3.36) follows

$$dg_{ij} = d(\mathbf{p}_{i+1} - \mathbf{p}_i) \cdot (\mathbf{p}_{j+1} - \mathbf{p}_j) + (\mathbf{p}_{i+1} - \mathbf{p}_i) \cdot d(\mathbf{p}_{j+1} - \mathbf{p}_j), \quad (1 \leq i, j \leq N) \quad (\text{A.14})$$
